SUMMARY

We propose a class of spherical wavelet bases for the analysis of geophysical models and for the tomographic inversion of global seismic data. Its multiresolution character allows for modelling with an effective spatial resolution that varies with position within the Earth. Our procedure is numerically efficient and can be implemented with parallel computing. We discuss two possible types of discrete wavelet transforms in the angular dimension of the cubed sphere. We describe benefits and drawbacks of these constructions and apply them to analyse the information in two published seismic wave speed models of the mantle, using the statistics of wavelet coefficients across scales. The localization and sparsity properties of wavelet bases allow finding a sparse solution to inverse problems by iterative minimization of a combination of the ℓ_2 norm of the data residuals and the ℓ_1 norm of the model wavelet coefficients. By validation with realistic synthetic experiments we illustrate the likely gains from our new approach in future inversions of finite-frequency seismic data.

Key words: Wavelet transform; Inverse theory; Seismic tomography.

1 INTRODUCTION

As long as tomographic earth models remain the solutions to mixed-determined (Menke 1989) inverse problems (Nolet 1987, 2008) there will be disagreement over the precise location, shape and amplitude of lateral and radial anomalies in seismic wave speed that exist within the Earth; there will be attempts to derive the best-fitting mean structure (e.g. Becker & Boschi 2002), and the needed efforts to validate them (e.g. Capdeville *et al.* 2005; Qin *et al.* 2009; Bozdağ & Trampert 2010; Lekić & Romanowicz 2011). At the same time, patterns, second-order structure and correlations between and within models will continue to be sought with the goal of characterizing seismic heterogeneities (e.g. Passier & Snieder 1995; Bergeron *et al.* 1999; Hernlund & Houser 2008) or relating them to geochemical (e.g. Gurnis 1986), tectonic (e.g. Yuen *et al.* 2002; Becker *et al.* 2006), or geodynamical (e.g. Jordan *et al.* 1993; Pìromallo *et al.* 2001; Houser & Williams 2009) processes. It has also become clear that model characteristics such as the power spectrum of tomographic anomalies (Chevrot *et al.* 1998a,b; Boschi & Dziewoński 1999) may teach us as much about the modeller's choices of parametrization and regularization as about the model, without imparting much information about the physical or statistical nature of our complex, physically and chemically differentiated system Earth—yet the latter should be our target. As pioneered by Gudmundsson *et al.* (1990) and Davies *et al.* (1992), in re-

cent work questions about the size and scale distribution of earth structure have more fruitfully been addressed by direct inference from the data themselves (e.g. Hedlin & Shearer 2000; Margerin & Nolet 2003; Becker *et al.* 2007; Garcia *et al.* 2009) without the detour of first deriving an imperfect 3-D model and analysing that.

By no means are the analysis and representation of volumetric properties the sole purview of seismology or geodynamics, and thus it is not surprising that there is a large literature on the subject in virtually every area of scientific inquiry (e.g. medical imaging, astronomy, cosmology, computer graphics and image processing). While in prior seismological work the mathematical framework and terminology appropriate to discuss 'parsimonious' parametrizations to solve inverse problems may not have been as explicit, approaches using irregular parametrizations, either in a static (chosen in advance) or dynamic (adapted to the data constraints during the inversion) sense have touched upon many aspects of the problem with which we will concern ourselves here (see, e.g. Sambridge & Rawlinson 2005, and references therein), and so have several techniques that pertain to inversions using model 'simplicity' as explicit constraints (e.g. Pulliam *et al.* 1993; Vasco *et al.* 1994, 1999).

In this context much has come to be expected of the special powers of wavelets, with their built-in discriminating sensitivity to structure in the space and spatial-frequency domains (Daubechies 1992; Strang & Nguyen 1997; Mallat 2008). Notwithstanding a

continued interest and clear and present progress in the field (e.g. Foufoula-Georgiou & Kumar 1994; Klees & Haagmans 2000; Freeden & Michel 2004b; Oliver 2009), the use of wavelets is still no matter of routine in the geosciences, beyond applications in one and two Cartesian dimensions. This despite, or perhaps because, there being a wealth of available constructions relevant for global geophysics, in other words: on the sphere (e.g. Schröder & Sweldens 1995; Narcowich & Ward 1996; Antoine *et al.* 2002; Holschneider *et al.* 2003; Freeden & Michel 2004a; Fernández & Prestin 2006; Hemmat *et al.* 2005; Schmidt *et al.* 2006; Starck *et al.* 2006; McEwen *et al.* 2007; Wiaux *et al.* 2007; Lessig & Fiume 2008; Bauer & Gutting 2011), if not on the ball. Indeed, inasmuch as they involve the analysis of cosmological data, satellite observations or computer-generated images, the above studies are mostly concerned with surfaces, not volumes.

In seismology, Chiao & Kuo (2001) were, to our knowledge, the first to develop a ‘biorthogonal-Haar’ wavelet lifting scheme (Schröder & Sweldens 1995) for a triangular surface tessellation of the sphere suitable for multiscale global tomography. Later, these same authors formed a (biorthogonal) spline basis for a Cartesian cube useful in exploration geophysics (Chiao & Liang 2003) and for regional studies (Hung *et al.* 2010). Finally, Chevrot & Zhao (2007) constructed a 3-D (orthogonal) Haar basis on an equidistant geographical grid that was also used for a regional inversion. To this date, a truly 3-D wavelet basis on the ball with practical utility in the geosciences has been lacking.

Whatever the role that wavelets will play in it, the future of global seismic tomography will involve massive amounts of heterogeneous data spanning a range of resolutions, from traveltimes reported by global networks to waveforms of portable deployments, with strong regional concentrations of station coverage in areas such as Japan, the United States and Europe, supplemented with sparse networks in less densely populated or oceanic regions. It is also clear that finite-frequency kernels, which allow for the correct volumetric sensitivity-based weighting of the measurements in distinct frequency bands, are here to stay, whichever the various ways in which they are calculated (see Nolet 2008). Accounting for finite-frequency sensitivity requires an effective overparametrization to exploit the extra resolution offered by the spatial variations in sensitivity: for this wavelets seem ideally suited also.

This paper documents the extensive prospective work that we have done in preparation for realistic wavelet-based global seismic inversions. Our goal remains to ensure that there exist performant and efficiently calculable, flexible wavelet methods on the 3-D ball to fulfill the promise of multiresolution analysis (Mallat 1989; Jawerth & Sweldens 1994) in global seismology. Not just for the representation and analysis of seismic models after the fact, but rather for their determination, as an integral part of a parsimonious parametrization of the inverse problem—of the sensitivity matrix, of the model space, or both. Although there is no objective guarantee that Nature, or the interior of the Earth in particular, are parsimonious in character, sparsity is worth striving for. By simplifying a tomographic image to contain a relatively small number of recognizable objects we facilitate interpretation (Sambridge *et al.* 2006). Moreover, such models can be more accurate than their data (Gauch 2003), a point not to be overlooked in view of the large relative errors of seismic delay times and amplitudes.

By ‘flexibility’ we mean the ability to substitute one particular wavelet design for another in any of the three coordinate directions; by ‘efficiency’ we intend to avoid the case-by-case derivation of different bases and calculation methods. By ‘performance’ we target the ability to capture the unknown model by explaining the

data (in an ℓ_2 sense) with a minimum of wavelet and scaling coefficients, both where the data require the solution to be smooth and where they necessitate the presence of sharp contrasts. It is of course in this capacity also (e.g. Donoho & Johnstone 1994, 1995) that wavelets will distinguish themselves from many other traditional methods of seismic inversion (except, perhaps, Bayesian partition modelling and related methods, see Denison *et al.* 2002; Bodin *et al.* 2009; Bodin & Sambridge 2009). As to ‘sparsity’, it is both numerically and philosophically attractive (Constable *et al.* 1987) and physically plausible or at least testable that the interior of the Earth should be sparse when expressed in a wavelet basis. Fortunately, for most large underdetermined systems of linear equations the minimal ℓ_1 norm solution is also the sparsest (Candès *et al.* 2006; Donoho 2006), and (fast, iterative) algorithms are available (Daubechies *et al.* 2004; Loris 2009). Elsewhere, Loris *et al.* (2007, 2010) and Gholami & Siahkoobi (2010) explored the suitability of sparsity-seeking thresholded wavelet-based inversion approaches in 2-D and 3-D Cartesian settings relevant to seismic tomography. All of the above issues will be the guiding principles behind the new spherical wavelet construction(s) that we present in this paper.

This paper is organized as follows. In Section 2 we develop a first class of wavelet constructions on the sphere via a well-known Cartesian-to-spherical mapping known as the ‘cubed sphere’ (Ronchi *et al.* 1996; Komatitsch & Tromp 2002). As this surface tessellation has ‘seams’ separating each of six subdivisions or ‘chunks’, we acknowledge these boundaries in the construction by using so-called ‘wavelets on the interval’. These revert to the classical compactly supported (bi)orthogonal Cartesian constructions of Daubechies (1988) and Cohen *et al.* (1992) in the interior domains but receive special consideration on the edges as put forth by Cohen *et al.* (1993). In Section 3 we study the sparsity of two global seismic tomographic earth models by thresholded reconstructions of their wavelet transforms applied to the angular coordinates of the cubed sphere, at constant depth intervals, and considering a variety of goodness-of-fit criteria. We furthermore characterize, in Section 4, the scale lengths of heterogeneity in these models by reporting the absolute and relative contributions of the wavelet and scaling coefficients in their expansion as a function of depth and location in the Earth. We calculate the correlation of both models as a function of scale and position, and where this appears sensible, present estimates for the variable $\delta \ln V_s / \delta \ln V_p$ ratios that can be derived from it. Sections 3 and 4 are relatively self-contained and discuss aspects of geophysical interest that are not properly part of the mathematical treatment of the tomographic inverse problem. Readers with an interest limited to the latter will appreciate the motivation for our approach from these sections but may wish to skip them for a first reading. In Section 5 we review the main approach to obtain sparse wavelet-based solutions to the inverse problem of seismic tomography, which were previously discussed in a Cartesian framework by Loris *et al.* (2007, 2010). As using the first construction with such schemes led to undesirable artefacts at the edges between the chunks, we derive a second wavelet construction in Section 6, which appears to be free of such artefacts, as we show using realistic synthetic tests in Section 7. As we envisage it, the first wavelet construction remains the tool of choice for the analysis of seismic earth models, whereas the second construction is an adaptation that should be used in the inversion for such models from primary data. While we have focused on the angular part of the cubed ‘sphere’ we have generalized our construction to the case of the ‘ball’ and provide an outlook for further research in global seismic tomography in the concluding Section 8.

2 A FIRST CONSTRUCTION

Simple latitude–longitude grid coverings of the sphere are very inhomogeneous and suffer from meridian convergence and singularities at the poles (e.g. Swinbank & Purser 2006; González 2010; Lauritzen *et al.* 2010). For this reason no wavelet transform is ever expected to be naturally formulated in such traditional coordinates. As Ronchi *et al.* (1996), we define a coordinate quartet (ξ, η, r, κ) for each of the $\kappa = 1 \rightarrow 6$ chunks. The $-\pi/4 \leq \xi, \eta \leq \pi/4$ angular coordinates and the radial coordinate r are mapped to the usual Cartesian triplet (x, y, z) using the transformation

$$(x, y, z) = \begin{cases} r(\tan \eta, -1, -\tan \xi)/s & \text{if } \kappa = 1, \\ r(-1, -\tan \xi, \tan \eta)/s & \text{if } \kappa = 2, \\ r(\tan \eta, -\tan \xi, 1)/s & \text{if } \kappa = 3, \\ r(-\tan \xi, \tan \eta, -1)/s & \text{if } \kappa = 4, \\ r(1, \tan \eta, -\tan \xi)/s & \text{if } \kappa = 5, \\ r(-\tan \xi, 1, \tan \eta)/s & \text{if } \kappa = 6, \end{cases} \quad (1)$$

whereby $s = \sqrt{1 + \tan^2 \xi + \tan^2 \eta}$. The inverse mapping is obtained, for $t = \max(|x|, |y|, |z|)$,

$$(\xi, \eta, \kappa) = \begin{cases} [\text{atan}(z/y), \text{atan}(-x/y), 1] & \text{if } t = -y, \\ [\text{atan}(y/x), \text{atan}(-z/x), 2] & \text{if } t = -x, \\ [\text{atan}(-y/z), \text{atan}(x/z), 3] & \text{if } t = z, \\ [\text{atan}(x/z), \text{atan}(-y/z), 4] & \text{if } t = -z, \\ [\text{atan}(-z/x), \text{atan}(y/x), 5] & \text{if } t = x, \\ [\text{atan}(-x/y), \text{atan}(z/y), 6] & \text{if } t = y, \end{cases} \quad (2)$$

whereby $r = \sqrt{x^2 + y^2 + z^2}$. This parametrization is non-smooth across the edges separating the chunks. The above formulae correspond to the drawing in Fig. 1, where only one of the chunk faces is gridded to reveal the angular coordinate lines (ξ, η) at a resolution that divides this face into $2^4 \times 2^4$ distinct surface elements.

Figure 1. Aerial view showing our first adaptation of the cubed sphere of Ronchi *et al.* (1996). Of the front-facing five of the in total six ‘chunks’, one is gridded to reveal its 2^N distinct surface elements ($N = 4$).

Throughout this paper we will quote N as the angular resolution level of our cubed sphere, which implies that it has 6×2^{2N} such elements, with typical tomography grids having $N = 7$.

In principle there are many possibilities to choose the surficial coordinates (ξ, η) in each chunk. We picked ours to minimize the splitting of continents over more than one chunk. Our choice differs from the canonical version of Ronchi *et al.* (1996) by a rigid rotation of the coordinate system, as can be seen by comparing our Fig. 2 with their figs 15 and 16. The Euler angles used in our construction are $\alpha = 0.0339$, $\beta = 1.1705$ and $\gamma = 1.1909$, respectively. It is important to note that within a chunk ξ and η are not spherical coordinates; a shift in ξ (with η fixed) or in η (with ξ fixed) does not correspond to a rotation on the sphere. This is apparent from the pinching of coordinate lines in Fig. 1.

Armed with the coordinate conversions of eqs (1) and (2) we are able to regard the problem of designing a wavelet transform for the sphere as simply requiring the selection of a certain Cartesian wavelet transform, which is mapped to and from the sphere. Despite superficial similarities, our approach is different from that by Antoine & Vandergheynst (1999), Antoine *et al.* (2002) and Wiaux *et al.* (2005); the fundamental domain of our transform remains a single chunk. Within each such chunk, the surface Jacobian of our mapping is given by the smoothly varying

$$\mathcal{J}(\xi, \eta) = (1 + \tan^2 \xi)(1 + \tan^2 \eta)/s^3, \quad 1/\sqrt{2} \leq \mathcal{J} \leq 1. \quad (3)$$

For each of the chunks then, the area is given by

$$\int_{-\pi/4}^{\pi/4} \int_{-\pi/4}^{\pi/4} \mathcal{J}(\xi, \eta) d\xi d\eta = \frac{4\pi}{6}. \quad (4)$$

Without this being a uniform mapping, one of the main advantages of the chosen coordinate system is thus that the meshes defined on each region span the surface of the sphere with an almost constant spatial resolution, as noted by Ronchi *et al.* (1996).

Ignoring any and all such distortions we are able to unlock the power of popular Cartesian wavelet constructions, of which we choose the two best known: the orthogonal construction of Daubechies (1988) and the biorthogonal construction of Cohen *et al.* (1992). Both of these lead to compactly supported wavelets and scaling functions, though only the biorthogonal ones can be (anti)symmetric (except for Haar). Examples of scaling functions and wavelets at scales of decreasing dominant wavelength are shown in Fig. 3 for the four-tap Daubechies basis (D4) and in Fig. 4 for the Cohen–Daubechies–Feauveau family with four and two vanishing moments (CDF 4–2) in analysis and synthesis, respectively. To get a sense of the physical size of wavelets and scaling functions at a certain scale, which depends on the original cubed-sphere resolution parameter N , we calculate reference circles of various angular radii Δ , and quote their values in degrees above each panel.

The literature on Cartesian wavelet analysis is vast, and it is not our intention to repeat any of it here. Most useful for the practicing geophysicist will perhaps be the treatises by Mallat (2008) and Strang & Nguyen (1997); texts focused on algorithms are Press *et al.* (1992) and, in particular, Jensen & la Cour-Harbo (2001). All of the computer code required to reproduce the figures and conduct the analyses presented in this paper is moulded after these general references and will be available from the authors.

Two aspects of wavelet analysis bear specific mentioning here. The first intricacy is how we treat the seams between the chunks. In agreement with Cohen *et al.* (1993) the argument is easily made that neither ignoring the seams nor periodization or reflection are viable

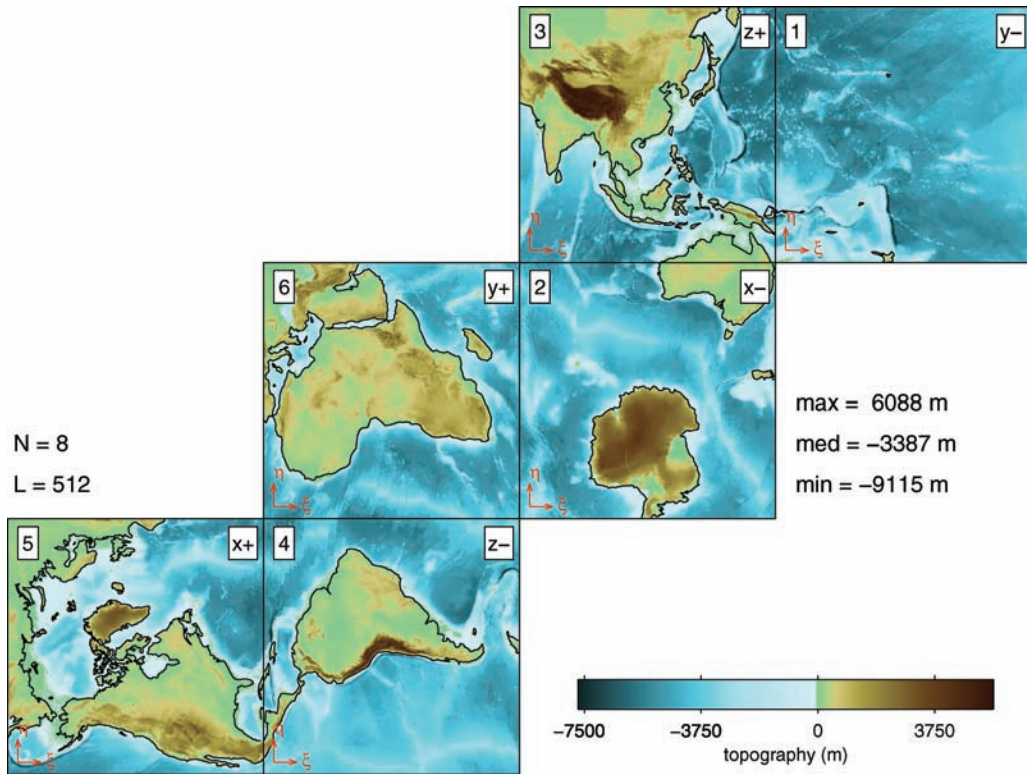

Figure 2. Geometry, nomenclature, and numbering of the six faces of our first adaptation of the cubed sphere of Ronchi *et al.* (1996) in a 2-D ‘unfolded’ view. Rendered is the Earth’s topography from the model ETOPO5, courtesy of NOAA’s National Geophysical Data Center. The projection was obtained by spherical-harmonic expansion of the coefficients from this model (Georg Wenzel, personal communication, 1999) truncated at degree and order $L = 2^{N+1}$, evaluated at the 6×2^{2N} cubed-sphere grid points ξ, η , for $N = 8$. Minimum, median and maximum values in this approximation are shown in the legend.

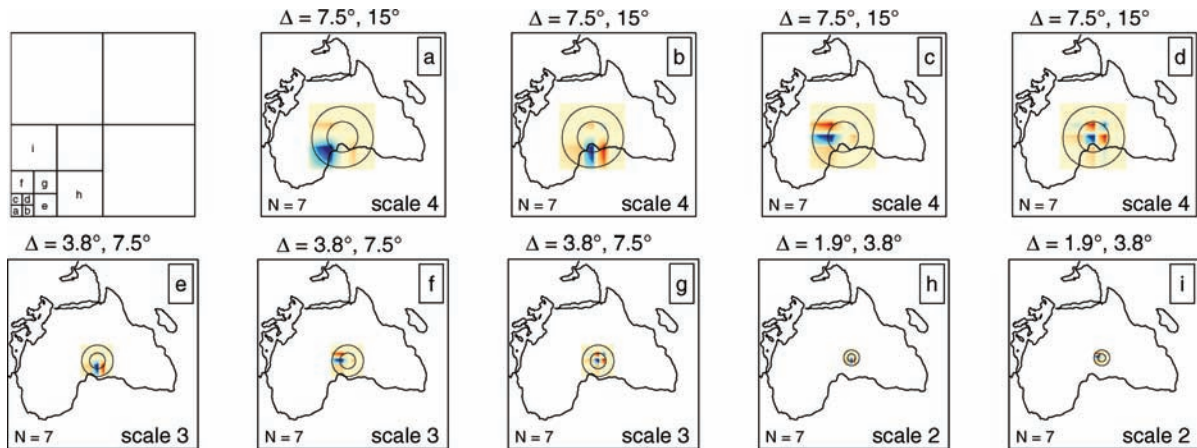

Figure 3. Wavelet and scaling functions of the D4 construction in the angular coordinates of the $N = 7$ cubed sphere, at various scales up to $J = 4$. Continental outlines and circles of varying angular radii Δ are plotted to make reference to physical spatial scales. The positions of the coefficients belonging to the functions in the lettered panels are shown in the diagram in the top left. The scaling function (a), which is averaging in nature, captures what remains to be explained after the breakdown into wavelets down to scale 4 is complete. Each of the wavelets, which pick up detailed, derivative, structure, is sensitive in a particular direction: to ξ in (b), to η in (c) or diagonally in (d). In the interior, away from the edges where boundary functions (not shown) live, the patterns repeat exactly, with the footprint at each successive scale half that of the preceding scale. The diagonally sensitive wavelet at scale 2 is not shown. Every function is orthonormal in (ξ, η) and their inner products with respect to every other one vanish. The symmetric colour scheme is 75 per cent saturated.

options, as each of these leads to artefacts in the representation. We thus follow their suggestion to the letter and construct a multiresolution basis requiring 2^{2N} wavelet and scaling coefficients for each of the chunk faces having 2^{2N} surface elements. For this we switch to special boundary filters at each of the edges, and apply preconditioners to the data prior to transformation to guarantee the usual

polynomial cancellation throughout the closed rectangular interval. The acknowledgment of the edges in this way is the hallmark of the wavelet construction in this section here (which we call the First Construction). This is as easily done for the orthonormal as for the biorthogonal constructions, though we have limited the implementation and illustration of this procedure, in Fig. 5, to the compactly

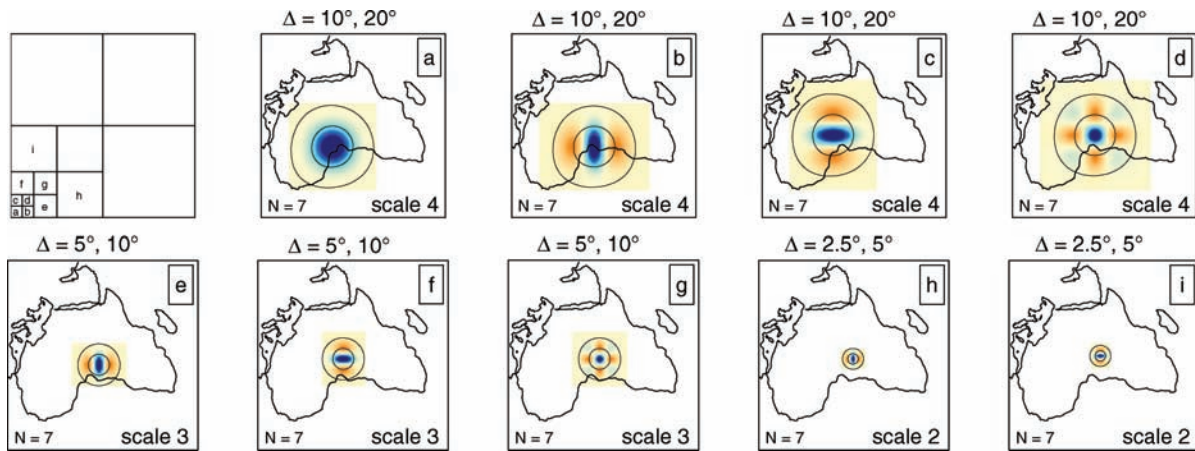

Figure 4. Wavelet and scaling functions arising from the CDF 4–2 construction in the angular coordinates of the cubed sphere, with their scale levels indicated. The layout is identical to that of Fig. 3. As opposed to the D4 wavelets, the CDF 4–2 construction is biorthogonal, which renders every shown synthesis function orthogonal in (ξ, η) to its dual, which is used for analysis; none of the dual functions are shown. Unlike the D4 functions the CDF 4–2 have mirror symmetry.

supported two-tap (Haar), four-tap and six-tap orthonormal families (D2, D4 and D6).

Before we discuss Fig. 5 in any more detail we should introduce the second important feature that renders wavelet transforms in general useful for the analysis and representation of (geophysical) data. This is the idea of ‘thresholding’, or ‘shrinkage’. In many applications wavelet transformation amounts to a projection under which many of the expansion coefficients are very small: so small that we might as well throw them away; the resulting reconstruction will still be close to the original (Donoho & Johnstone 1994). Intuitively, the ‘best’ wavelet basis that we can select to represent our data is the one that yields the most near-zero coefficients. When these are replaced by zeroes prior to reconstruction, as under the definition of ‘hard’ thresholding (Mallat 2008), we obtain highly compressed versions of the data at hand, with only negligible degradation.

Fig. 5 explores the effects of thresholding, coefficient statistics and reconstruction errors for a model of terrestrial topography, a general proxy for the length scales of heterogeneities to be found not only at the surface, but also in the interior of the Earth. We focus on the sixth, or ‘African’ chunk of our cubed sphere, and use the D2, D4 and D6 wavelet bases (on the interval, with preconditioning). The top row uses the (common) conventions introduced in Fig. 3 in plotting the wavelet and scaling coefficients in each of the bases after (hard) thresholding them such that only the coefficients larger than their value at the 85th percentile level survive. The coefficients that have now effectively been zeroed out are left white in these top three panels. The middle series of panels of Fig. 5 plots the spatial reconstructions after thresholding at this level; the rms errors of these reconstructions are quoted as a percentage of the original rms signal strengths. The thresholded wavelet transforms allow us to discard, as in these examples, 85 per cent of the numbers required to make a map of African topography in the cubed-sphere pixel basis: the percentage error committed is only 5.8 per cent, 4.9 per cent and 6.7 per cent according to this energy criterion in the D2, D4 and D6 bases, respectively. From the map views it is clear that despite the relatively small error, the D2 basis leads to block artefacts in the reconstruction, which are largely avoided in the smoother and more oscillatory D4 and D6 bases. A view of the coefficient statistics is presented in the lowermost three panels of Fig. 5. The coefficients are roughly log-normally distributed, which helps explain the success of the thresholded reconstruction

approach. While the example here was strictly designed to illustrate our algorithms and procedures, we conclude that the D4 basis is a good candidate for geophysical data representation, provided the edges between cubed-sphere chunks are properly accounted for.

3 EARTH MODEL SPARSITY

In tomographic studies, either as an integral part of the inversion or after a solution has been found, the target model is parametrized by local or global basis functions (Nolet 2008). Blocks, cells, nodes or voxels (e.g. Aki *et al.* 1977; Zhang & Tanimoto 1993; Spakman & Bijwaard 2001; Simons *et al.* 2002; Debayle & Sambridge 2004; Nolet & Montelli 2005) are all strictly local functions. Cubic B-splines (e.g. Wang & Dahlen 1995; Wang *et al.* 1998; Boschi *et al.* 2004) or wavelets (e.g. Chiao & Kuo 2001; Chevrot & Zhao 2007; Loris *et al.* 2007) are more generally localized functions. Spherical harmonics (e.g. Dziewoński 1984; Woodhouse & Dziewoński 1984; Ekström *et al.* 1997; Trampert & Woodhouse 1996, 2001) are ideally localized spectrally but have global support (Freedman & Michel 1999). An intermediate approach that combines spatial and spectral localization was developed using spherical harmonic splines by Amirbekyan & Michel (2008) and Amirbekyan *et al.* (2008), but this produces an inverse problem that scales as the square of the number of data collected, rendering it impractical for the large-scale tomographic systems of the future.

In preparing for the study of the suitability for solution of such massive inverse problems of the wavelet transforms that we introduced in the previous section, we take a detour in this section by addressing the question: is the Earth sparse in a wavelet basis? Of course we will never be able to answer this question with any degree of certainty, but we can investigate, at the very least, whether earth models are sparse in such bases. Because they are, as we shall see, we will gain by parametrizing the inversion for future earth models using the spherical wavelets developed in this paper. The expected gains are with respect to numerical efficiency but also in terms of regularization. Since wavelets are not global functions (ours, as can be seen from Figs 3 and 4, are compactly supported, i.e. vanishing outside their scale-dependent footprint), and yet, (bi)orthogonal, the function basis will not dictate the model structure in areas of poor data coverage as is the case with spherical harmonics (Trampert & Snieder 1996; Boschi & Dziewoński

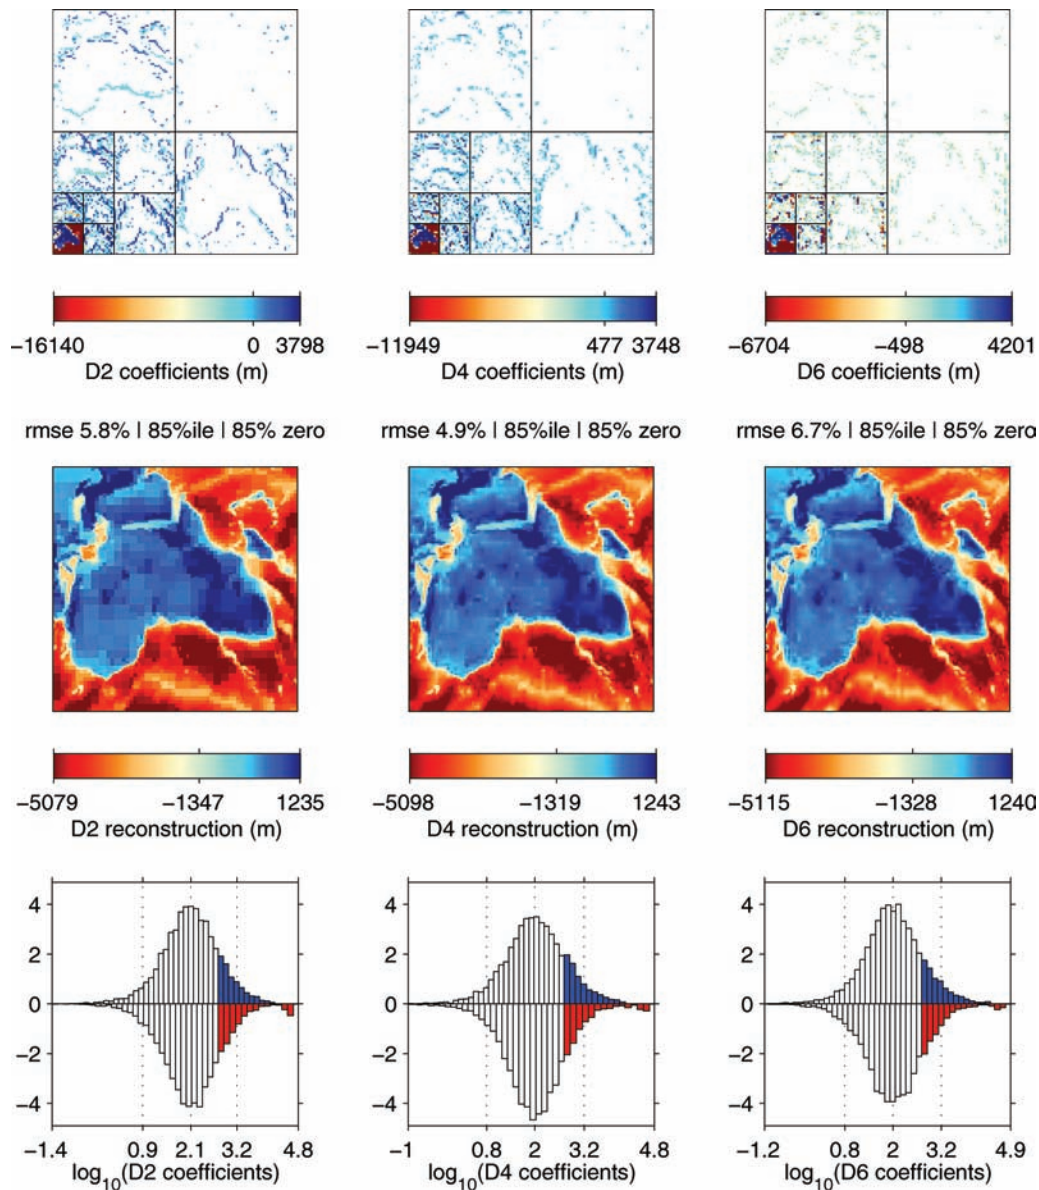

Figure 5. Wavelet and scaling coefficients (top panels), space-domain reconstructions after thresholding (middle panels) and 'signed' histograms (bottom panels) of the wavelet and scaling coefficients of the 'African' (sixth) face of the cubed-sphere version of the Earth's topography first shown in Fig. 2, to a 2^J dyadic subdivision with $J = 3$. We have used the preconditioned interval wavelet transforms on the faces of the cubed sphere, as described in the text. All coefficients were hard-thresholded at the 85th percentile level, retaining only the 15 per cent largest coefficients by absolute value. In the top row, the locations of zeroed coefficients are rendered white; those are also captured by the white bars in the histograms. The rms error of the reconstruction after thresholding is indicated as a percentage of the signal rms. Tick marks on the colour bars identify the 5th, 50th and 95th percentile of the coefficients or the spatial reconstructions after thresholding, respectively. Interior ticks on the histograms roughly coincide with these same percentiles as applied to either the positive and negative coefficients when expressed on a logarithmic scale. Histograms of the positive coefficients point up and have ordinates in positive percentages, those of the negative coefficients point down and have negative ordinates; these percentages are with respect to the total number of positive and negative coefficients. The blue and red shaded areas of the histograms reflect the coefficients retained at the 85th thresholding percentile.

1999; Amirbekyan *et al.* 2008). Moreover, though this depends on precisely which wavelet construction is being used, they are capable of representing smoothly varying functions as well as preserving sharp edges, and their natural multiresolution nesting will allow for the model resolution to vary spatially, as required by the data.

There is, however, another reason to find out how seismic earth models behave under wavelet transformation: because it enables us to study the relative importance of model heterogeneity at different scale lengths, which is important to help constrain geochemical and

geodynamical models and interpretations of earth structure. The Earth is heterogeneous at all scales but not likely everywhere to the same degree; thermally induced deviations from the radial average 1-D Earth structure are expected to be smoother and have longer wavelengths than those due to compositional variations; the presence of distinct scatterers further complicates this picture (Shearer & Earle 2004). In short, we are interested in obtaining a power spectral density of sorts (Chevrot *et al.* 1998a,b; Boschi & Dziewoński 1999), as applied to seismic structure and how it may vary spatially within the Earth. As we are not in the position to return to direct

measurements of the energy distribution of heterogeneity (Hedlin & Shearer 2000; Margerin & Nolet 2003; Becker *et al.* 2007; Garcia *et al.* 2009) we will instead study the sizes and scales within reported tomographic earth models.

From the multitude of seismic earth models that are available to study, we select two mantle models: one by Montelli *et al.* (2006) of compressional (P) wave speed heterogeneity and another by Ritsema *et al.* (2010) of shear (S) wave speed perturbations. Neither model has much at all in common with the other in terms of its construction, and from the point of view of parametrization, Montelli's model has a tetrahedral grid underlying it, whereas Ritsema's expands wave speed anomalies in a spherical harmonic basis complete to degree and order 40. At a depth of about 400 km, Figs 6(a) and (f) show P -wave (Montelli *et al.* 2006) and S -wave (Ritsema *et al.* 2010) anomalies from the average at that depth. Montelli's model was interpolated (from the tetrahedral grid on which it was built) onto the 6×2^{2N} ($N = 7$) points of our cubed sphere, whereas Ritsema's model was evaluated (from the listed spherical harmonic and radial spline expansion coefficients) at these same points. Subsequently, the wavelet transform in the D4 basis (with special boundary filters and after preconditioning, and up until scale $J = 3$) was thresholded and the result re-expanded to the spatial grid, identically as we did for the topography in Fig. 5. The results for specific values of the thresholding (quoted as the percentile of the original wavelet coefficients) are shown in Figs 6(a) and (g) for the 50th, Figs 6(c) and (h) for the 85th, Figs 6(d) and (i) for the 95th percentile, respectively. At each level of thresholding the number of non-zero wavelet or scaling expansion coefficients is quoted: at 0 per cent thresholding this number is identical to the number of pixels in the surficial cubed sphere being plotted.

As we have written before, the wavelet transformation does not change the number of pieces of information with which it is presented. Rather, it dramatically redistributes information in a manner that allows us to simply omit those coefficients with low values, with limited degradation to the spatial field being represented. This reconstruction error can be visually assessed from the pictures; it is also quoted next to each panel as the percentage of the rms error between the original and the reconstruction, normalized by the rms value of the original in the original pixel representation, in per cent. Specifically, we calculate and quote the ratio of ℓ_2 norms in the pixel-basis model vector \mathbf{m} ,

$$100 \times \|\mathbf{m} - S\{\mathcal{T}[A(\mathbf{m})]\}\|_2 / \|\mathbf{m}\|_2, \quad (5)$$

which, in the lower-right annotations is called the per cent error norm. We have written A for any of the wavelet (analysis) transforms that are used and S (synthesis) for their inverses, and \mathcal{T} for the hard thresholding (Mallat 2008) of the wavelet and scaling coefficients.

In Figs 6(e) and (j), this same misfit quantity (5) is represented as a black line relevant to the left ordinate labelled ' ℓ_2 error norm', which shows its behaviour at 1 per cent intervals of thresholding; the filled black circles correspond to the special cases shown in the map view. Only after about 80 per cent of the coefficients have been thresholded does the error rise above single-digit percentage levels, but after that, the degradation is swift and inexorable. The blue curves in Figs 6(e) and (j) show another measure relevant in this context, namely the ratio of the ℓ_1 norms of the thresholded wavelet coefficients compared to the original ones, in per cent, or

$$100 \times \|\mathcal{T}[A(\mathbf{m})]\|_1 / \|A(\mathbf{m})\|_1. \quad (6)$$

As we can see from the figure the ℓ_2 ratios (5) in the black curves (and the left ordinate) evolve roughly symmetrically to the ℓ_1 ratios

(6) in the blue curves (and the right ordinate), though evidently their range is different.

Finally, a third measure that is being plotted as the red curve is the 'total variation' norm ratio, in per cent, namely

$$100 \times \|\nabla S\{\mathcal{T}[A(\mathbf{m})]\}\|_1 / \|\nabla \mathbf{m}\|_1, \quad (7)$$

whereby $\|\nabla \mathbf{m}\|_1$ is the sum over all voxels of the length of the local gradient of \mathbf{m} . By this measure, which is popular in image restoration applications (Rudin *et al.* 1992; Dobson & Santosa 1996; Chambolle & Lions 1997), the quality of the reconstruction stays very high even at very elevated levels of thresholding; we note that its behaviour is not monotonic and may exceed 100 per cent.

As with terrestrial topography in Fig. 5 we conducted all of the experiments on the seismic models that are presented in Fig. 6 in the D2, D4 and D6 wavelet bases. A summary of the ℓ_2 error norm ratios as a function of thresholding levels for each of those bases is presented in Table 1. On the strength of its behaviour under the criteria (5)–(7) and upon visual inspection of the results, we conclude that the D4 basis remains a very appropriate choice for the efficient representation of seismic models. To this choice we adhere in the geophysically motivated study of mantle structure in those same models which follows below.

4 TOMOGRAPHIC MODEL STRUCTURE

There is much geophysical interest in tying seismic observations of mantle structure to models incorporating geodynamic modelling and mineral physics observations (e.g. Jordan *et al.* 1993; Káráson & van der Hilst 2000; Becker & Boschi 2002; Bull *et al.* 2009). Our study is an attempt to provide a flexible, quantitative, multiresolution framework for such analyses that may add to the more traditional power-spectral (e.g. Becker & Boschi 2002; Houser & Williams 2009; Schuberth *et al.* 2009) and statistical analyses (e.g. Hernlund & Houser 2008). In obliterating the phase of the anomalies, the former line of inquiry largely loses the relative spatial location of seismic structure, while the latter type of study is no longer sensitive to its scale or wavelength dependence. While in this paper we do not explicitly study the radial correlation of mantle structure (Puster *et al.* 1995; van der Hilst & Káráson 1999), the analysis readily lends itself to adaptation in the third dimension: our study is thus as much an initial exploration into the richness of the wavelet transform as a way of characterizing terrestrial heterogeneity as an encouragement to further study.

The first breakdown is as a function of depth and by scale of the D4 decomposition, as shown in Fig. 7. To aid in the interpretation we remind the reader of the dominant wavelengths that are represented at a specific scale by referring to Fig. 3, where of course it should be noted that the area of the panels decreases with the square of the depth in the Earth.

The main observations relevant to both the Montelli *et al.* (2006) and Ritsema *et al.* (2010) models are that seismic wave speed heterogeneity has a dominantly 'red' spectrum (Chevrot *et al.* 1998a,b; Boschi & Dziewoński 1999). Figs 7(a) and (c) show the maximum absolute values of the wavelet and scaling coefficients at each of the four scales in the D4 decomposition, as a function of depth. The scaling functions at scale 4 (denoted 'scals 4' in the legend; these are depicted in Fig. 3a) require the largest expansion coefficients; the maxima of the coefficients corresponding to the wavelets at scale 4 ('wavs 4', see Figs 3b–d) are only about half as large; those at scale 3 ('wavs 3', see Figs 3e–g) peak at about half that; and so on. While noting that the Montelli model has peak amplitudes for V_P that are about half as large as the ones for V_S in the Ritsema model,

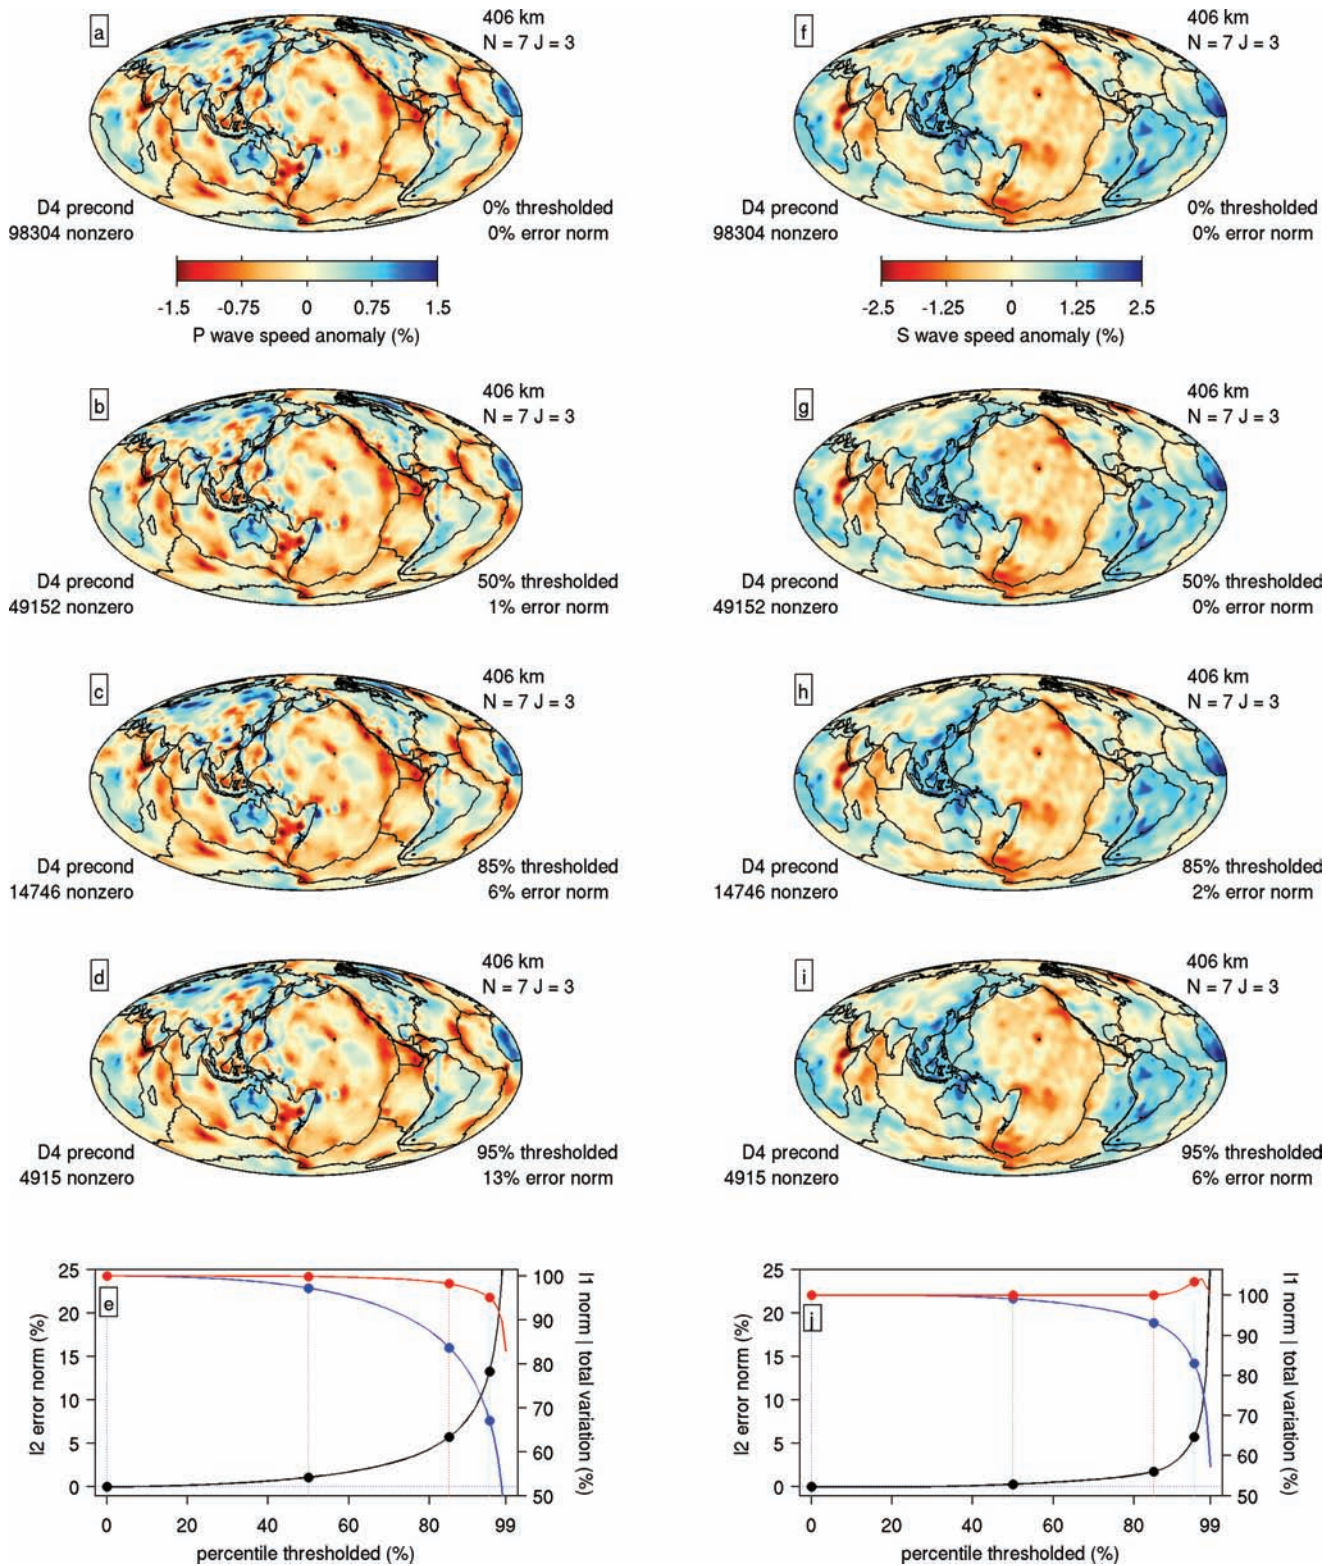

Figure 6. Sparsity and reconstruction stability of two global seismic wave speed models under incremental hard thresholding of their wavelet and scaling coefficients using the preconditioned edge-cognizant D4 wavelet basis (Daubechies 1988; Cohen *et al.* 1993) in the angular coordinates of the cubed sphere, as developed in this paper. (a–e) Results for the *P*-wave seismic model of Montelli *et al.* (2006) and (f–j) for the *S*-wave seismic model of Ritsema *et al.* (2010), at the same depth of 406 km below the surface of the Earth, for cubed spheres with 6×2^{2N} elements ($N = 7$), and to a 2^J dyadic subdivision ($J = 3$). As a function of the percentage of the coefficients that are being thresholded, and relatively to the original unthresholded values, the bottom panels quote the spatial ℓ_2 norms of the reconstruction error (in black), the total variation norms of the reconstructed images in the space domain (in red) and the ℓ_1 norms of the coefficients that remain (in blue). The values obtained for the cases shown in map view are shown as filled circles on these graphs, and the corresponding metrics in the D2, D4 and D6 bases are tabulated in Table 1. The reconstructions remain faithful to the originals even at elevated levels of thresholding.

Table 1. A companion to Fig. 6, this table lists the ℓ_2 error norms, relative to the original, of the reconstructions of the P -wave speed model of Montelli *et al.* (2006) and the S -wave model of Ritsema *et al.* (2010) under hard wavelet thresholding in the angular coordinates. See Fig. 6 and text for more details.

Depth (km)	Thresholding percentile	Montelli <i>et al.</i> (2006)			Ritsema <i>et al.</i> (2010)

Figure 7. Scale lengths of seismic heterogeneity as a function of depth in the Earth, to the core–mantle boundary (CMB), obtained from the complete angular expansion in the D4 wavelet basis of (a–b) the P -wave speed model of Montelli *et al.* (2006) and (c–d) the S -wave speed model of Ritsema *et al.* (2010). See Fig. 3 for the wavelet and scaling functions and Fig. 6 for the seismic models; calculations are referenced to cubed spheres with 6×2^{2N} elements ($N = 7$), and to a 2^J dyadic subdivision ($J = 4$). Panels a and c show the maximum absolute values of the wavelet or scaling coefficients (‘wavs’ and ‘scals’ in the legend, respectively) at the scales quoted, differentiated by colour. The scaling coefficients at the fourth scale have the largest values: at all depths the maximum at this scale and the overall maximum (not shown) coincide. Panels b and d show the proportion (in per cent) of the contribution to the overall ℓ_2 norm of the seismic models at every depth by the ensemble of the coefficients at each of the scales. Ritsema’s model has much more structure in the top 410 km of the Earth (not shown because of the axis truncation is a peak with a value of 137.2 centred at 135 km) compared to the bottom 1000 km, as opposed to Montelli’s model which has a more uniform distribution of heterogeneity. Both models are characterized by minima of seismic structure at mid-mantle depths.

in both models the overall largest values are in the lithosphere, encompassing the crust and the shallowmost mantle down to about 250 km. The upper mantle (down to 660 km) and the transition zone (410–660 km) in particular are characterized by strong maxima that fluctuate with depth. Both seismic models have a somewhat different take on this measure of mantle structure: the maxima in the Ritsema model (Fig. 7c) are more oscillatory with depth and have a strong peak around the 660 km mantle discontinuity which is narrower than the corresponding one in the Montelli model (Fig. 7a).

Each of the curves in Figs 7(a) and (c) decays sharply with increasing depth in the lower mantle below 660 km depth to reach their smallest maxima in the mid-mantle before increasing again in the bottom 1000 km, near the core–mantle boundary (CMB). This identification of dominantly long-wavelength structure near the CMB (see also Wyssession 1996; van der Hilst & Kárasón 1999) is relatively more pronounced in the Montelli model than in Ritsema’s. In Montelli’s P -wave model (Fig. 7a) both scale 4 curves have significant ‘bumps’ near the CMB, while the corresponding increase in

maximum structure in Ritsema's S -wave model (Fig. 7c) is more gradual and confined mostly to the longest-wavelength scaling functions at scale 4 (see also Wyession *et al.* 1999).

The maximum values of the expansion coefficients in the wavelet basis provide but one part of interpretation of mantle structure, thus in Figs 7(b) and (d) we plot the percentage-wise relative contribution of the wavelet and scaling coefficients at each scale to the overall ℓ_2 norm of the respective seismic models. These curves again reveal the scale and depth dependence of mantle heterogeneity, but now in terms of how much variance is explained by each scale at every depth individually: each of the curves sums to very nearly 100 per cent at every depth. Their failure to sum to exactly 100 per cent arises from the preconditioning of the wavelet transforms at the edges, which renders even the D4 transforms slightly non-orthonormal overall; however, these small (<1 per cent) deviations are not sufficiently important to influence any of the interpretations. In this analysis we note that once again the relative contributions to model structure are more variable with depth in the Ritsema model (Fig. 7d) than in the Montelli model (Fig. 7b), which is particularly smooth in this regard. In both, however, the importance of the structure at wavelet-scale 4 grows as a function of depth to reach a maximum about one-third of the way down. This maximum is particularly well pronounced in Ritsema's model where it is well localized at the top of the lower mantle, between 660 km and 1000 km depth. The growth of wavelet-scale 4 structure comes at the expense of scaling-function scale 4 structure, suggesting that in that depth range long-wavelength heterogeneity is broken down to smaller scales.

Another window into the Earth's structural heterogeneity and a useful comparison between models come in the form of Fig. 8, where we are able to deconstruct both of the seismic models under consideration on a chunk-by-chunk basis. The (arbitrary and thus easily modified) choice we made in Fig. 2 to deviate from the canonical Ronchi *et al.* (1996) orientation of the cubed sphere by approximately centring each of the faces on a major continental landmass now allows us to study the relative contributions of the depth-dependent seismic structure broken down by preponderant scale length as a function of location in the Earth. Each of the curves originally plotted in Figs 7(b) and (d) degenerates to six individual ones with their own geographical affiliation. The numbering scheme is the one introduced in Fig. 2, thus in order of appearance, 1 corresponds to the Pacific realm, 2 to Antarctica, 3 to most of Asia, 4 to South America, 5 to North America and parts of Eurasia and 6 to Africa, the Middle East and the Arabian Peninsula. In the computer code that accompanies this paper, any other wholesale rotation may be applied to the master grid, for example, to undo the somewhat unfortunate splitting of Australia over chunks 2 and 3 and of Eurasia over chunks 3, 5 and 6. In other words, the cubed-sphere wavelet transform may be applied in 'detector' mode by rigid rotation to centre on any point of interest. Moreover, provided the scales to be analysed allow it, any geographical portion of the wavelet-transformed coefficients may be zeroed out to provide even more geographical selectivity without compromise. Such is the power derived from multiresolution and scale-space localization under the wavelet transform.

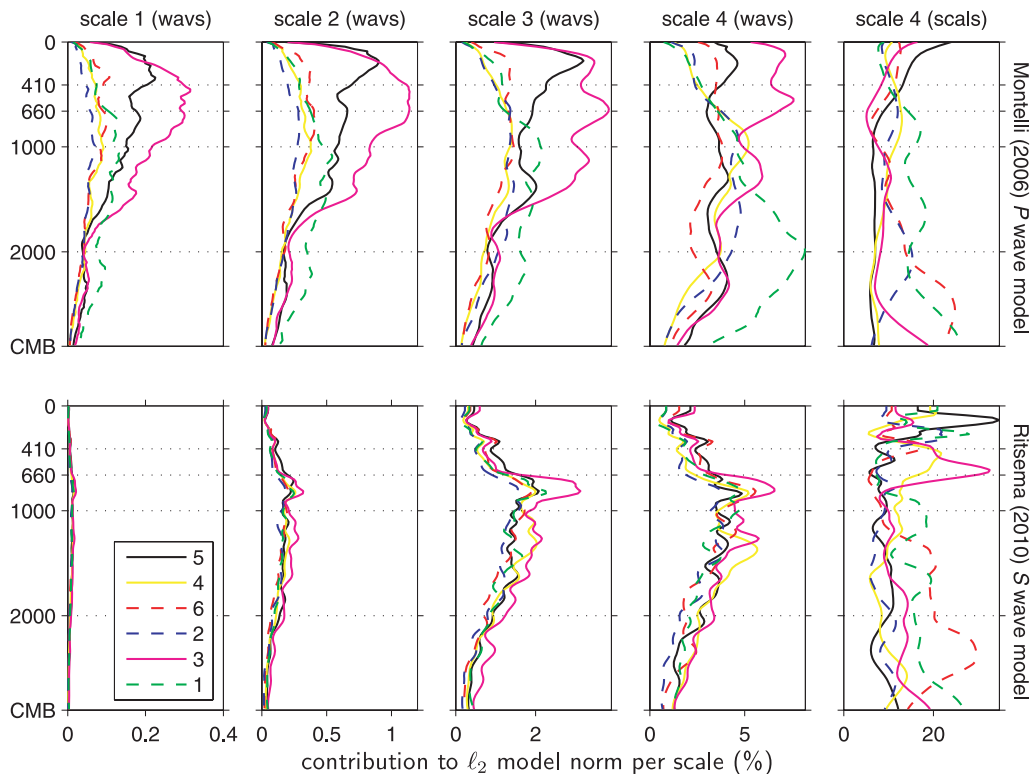

Figure 8. Scale lengths of seismic heterogeneity as a function of depth (km) in the Montelli *et al.* (2006) P -wave and the Ritsema *et al.* (2010) S -wave models. The calculations are identical to those reported in Fig. 7(b, d) but they are now broken down per cubed-sphere chunk to reveal geographical variations in seismic mantle structure. See Fig. 2 for the numbering scheme used in the legend identifying the colored lines: roughly speaking, 1 corresponds to the Pacific, 2 to Antarctica, 3 to Asia, 4 to South America, 5 to North America, and 6 to Africa. The relative lack of fine structure at scales 1 and 2 and the less geographically differentiated character at scales 3 and 4 of the Ritsema model clearly distinguish it statistically from the Montelli model. Other features are more persistent between models, such as the predominantly large-scale structure near the core–mantle boundary underneath Africa and the Pacific, and the predominantly smaller-scale features in the shallow mantle and crust underneath Asia and North America.

Among other features the results presented in Fig. 8 reveal how the dominantly long-wavelength structure near the CMB is mostly due to what lies beneath Africa and the Pacific: indeed these are regions that have been long known for being the source of various long-wavelength mantle upwellings or (super-)plumes (Ni & Helmberger 2003). As to Ritsema's (complete to spherical-harmonic degree 40) model, precious little mantle structure is present at the very shortest wavelengths of scale 2 (see Figs 3h and i) and scale 1 (whose footprint, not shown in Fig. 3, is exactly half that of scale 2). While also in Montelli's model the heterogeneity at these scales remains limited at the subpercentage level, there is considerably more energy that contributes to the model norm, and there is much more geographical variability between chunks in this latter model. The relative lack of a geographical signature when comparing Ritsema's to Montelli's model continues to be apparent at the larger scales 3 and 4; only at scale 4 do both models ascribe mantle structure with significant difference to each of the six gross mantle domains. Presumably this rather different character between both models is due to the data selection and model parametrization: Ritsema's model contains the effect of the whole-mantle sensitivity of normal-mode splitting functions and the spread-out influence of long-period surface waves. Moreover, this model is derived in terms of global spherical harmonics (Ritsema *et al.* 2010). The resolution gains from including spherical harmonic basis functions to degree and order 40 as compared to an earlier iteration of this model (Ritsema *et al.* 1999, 2004; Ritsema 2005) appear modest. Montelli's model, in contrast, contains only body-wave observations, albeit using finite-frequency sensitivity theory which notably 'fattens' their traditional, ray-theoretical, zone of influence (Montelli *et al.* 2004, 2006), and it is parametrized on a grid of tetrahedral nodes that, while globally distributed throughout the Earth's volume, allows for more degrees of freedom and hence spatial variability in the recovered seismic model. Undoubtedly the scale- and space-dependent breakdown of both models is also influenced by the different choices of damping and smoothing in the inverse problem that led to their construction (Boschi & Dziewoński 1999). Thus, while our analysis cannot claim to uncover the 'truth' in characterizing earth structure, it does however, endow us with a measurement tool for the multi-scale dependence of seismic model structure. This will serve as a target to reconcile such models with what we can learn from forward geodynamical modelling or in their confrontation with mineral physics observations (e.g. Mégnin *et al.* 1997; Piromallo *et al.* 2001; Cammarano *et al.* 2005; Piazzoni *et al.* 2007; Ritsema *et al.* 2007; Bull *et al.* 2009).

An even more detailed multiscale comparison between both seismic models involves the joint properties of their wavelet coefficients at all depths in the Earth. An example is shown in Fig. 9, where we report the correlation between wavelet coefficients in the Montelli and Ritsema models as a function of scale and approximate geographical position (see again Fig. 2 for the numbering scheme of the cubed-sphere chunks). A rendering of the 2-D density of the data is accompanied by the value of their correlation coefficient (lower left labels) where this is deemed significant at the 95 per cent level, and the slope of the total-least-squares-based fit in this space (upper right labels), which is only quoted when the correlation coefficients exceeded 0.35. This should provide an estimate of the logarithmic ratio of shear-wave to compressional-wave speed perturbations, $\delta \ln V_S / \delta \ln V_P$, an important discriminant in the interpretation of the (thermal or chemical) cause of seismic velocity anomalies (Masters *et al.* 2000; Trampert & van der Hilst 2005). The variation of this ratio as a function of scale and chunk position yields information that will be of use for geochemical and geody-

namical studies, and the orthogonality of the wavelet basis in scale and physical space removes some of the arbitrariness in the calculation. The depth of 474 km that we selected for illustration displays the largest overall correlation between both models.

The absence of information at the smallest scales 1 and 2 in Ritsema's model is now apparent from the top two rows in Fig. 9: invariably, the P anomalies from Montelli's model map to much smaller S perturbations in Ritsema's. From scale 3 onwards a positively correlated pattern begins to emerge, though at this particular scale, the correlation coefficients remain below the stringent 0.35 level that we have set for ourselves. Wavelets and scaling coefficients are rather well correlated at the largest scale 4 considered, with several of the correlation coefficients comfortably exceeding our threshold. The value of the $\delta \ln V_S / \delta \ln V_P$ ratios vary between about 1.5 and 4.5, which represents about half the range that they reach when all depths are being considered individually. This is in agreement with previous studies, for example, those by Tkalčić & Romanowicz (2002), Saltzer *et al.* (2001) and Deschamps & Trampert (2003). With these last two authors we emphasize how regionally variable such ratios are, and how ultimately, they remain dependent on data availability and modelling assumptions entering the production of independently derived P - and S -mantle models (Trampert & van der Hilst 2005). Robust as these determinations of $\delta \ln V_S / \delta \ln V_P$ ratios are using the wavelet decomposition scheme, our analysis has identified an additional dependence on scale length.

5 THE INVERSE PROBLEM

In the previous sections we have constructed a new wavelet transform on the 3-D ball. We have shown that, in a suitably chosen wavelet basis, earth models require few significant coefficients. We have used our wavelet scheme to deconstruct two tomographic earth models and evaluated those, both for their sparsity and to study the distribution of mantle structure as a function of scale, depth and geographical location. While we have argued that we can learn much from such exercises, we have only partially reached our end goal, which is to harness the power and performance of spherical wavelet bases to build new seismic tomographic models, directly from the data, which are expected to be sparse in such bases. In other words, we have not solved any inverse problems yet. In this section we explain how the new wavelets can be used to do that, too.

Wave speed models are constructed from seismic data. With respect to a reasonably sized global model parametrization these data are incomplete, as seismic stations are mostly concentrated in a limited number of regions around the globe—that is, until the oceanic arrays of the future come online (Simons *et al.* 2009; Vincent & Simons 2011). As usual we shall assume that a background velocity model is known, and that our goal is to solve the data for a perturbation $m(\mathbf{x})$ to that reference model. We may approximate the seismic observations,

$$\int_{\oplus} K(\mathbf{x}) m(\mathbf{x}) d^3 \mathbf{x} = d, \quad (8)$$

which are of the most general kind described by such integral equations and with K any of a veritable plethora of possible kernel functions (Nolet 2008), by the discretization on the grid defined in Section 2. This leads to an inverse problem in matrix form,

$$\mathbf{K} \cdot \mathbf{m} = \mathbf{d}, \quad (9)$$

where the aim is to reconstruct the model values \mathbf{m} from the data vector \mathbf{d} . The elements of \mathbf{m} are the values of the model inside of

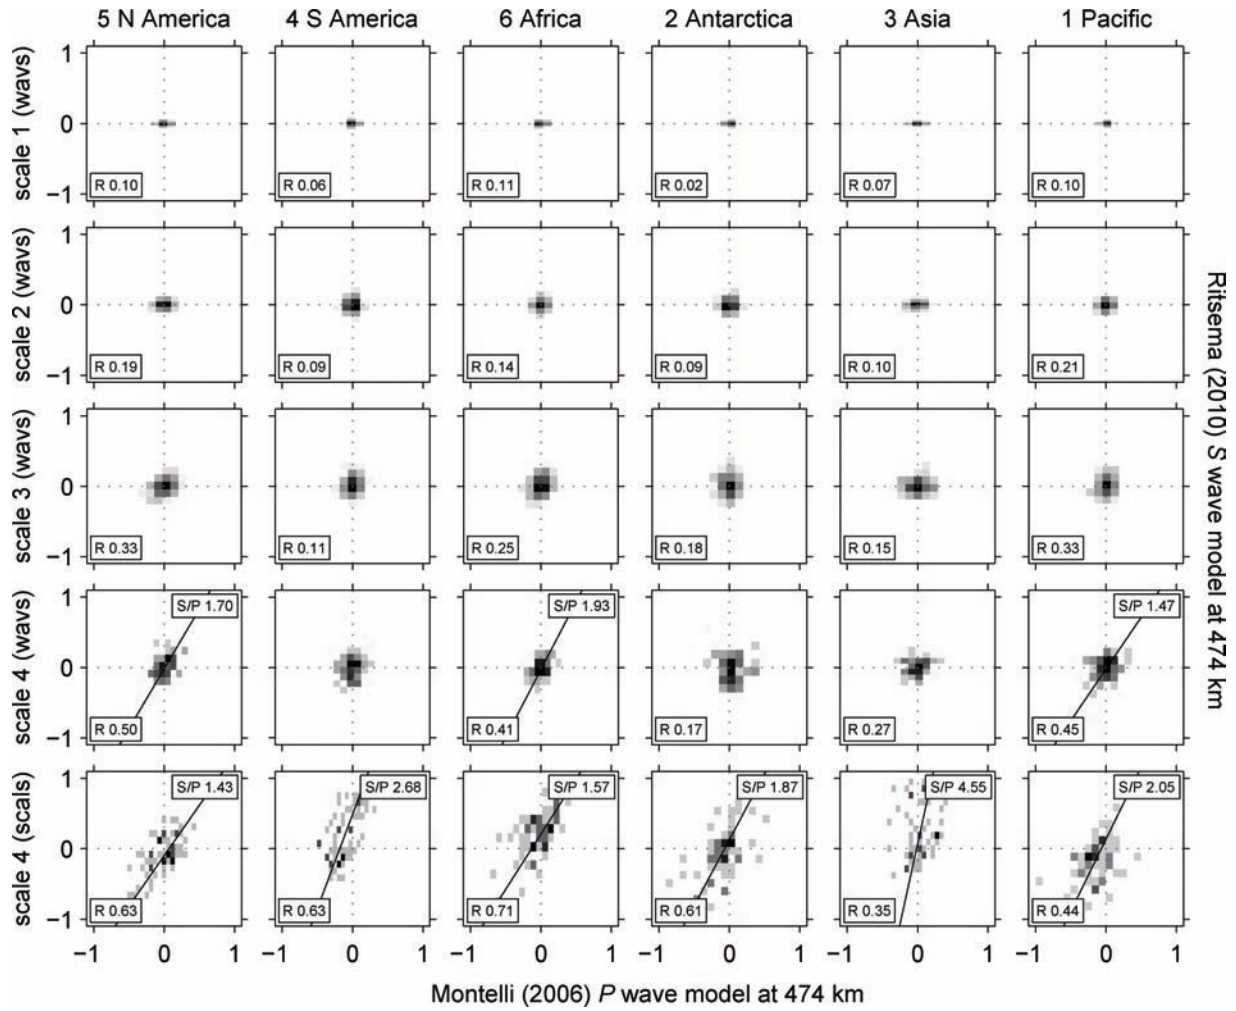

Figure 9. Joint properties of seismic mantle structure in the Montelli *et al.* (2006) *P*-wave and Ritsema *et al.* (2010) *S*-wave speed models, at 474 km depth in the Earth. Every row corresponds to a different scale in the D4 wavelet decomposition of the models. Each panel shows the logarithmic density of observations. Black shading corresponds to the maximum density in each panel; all patches that account for less than 1 per cent of the observations are rendered white. Using total-least-squares a regression line was fit to all sets with correlation coefficients exceeding 0.35. The slope of the line, a measure of the $\delta \ln V_S / \delta \ln V_P$ ratio, appears in the top right corners. Correlation coefficients are quoted in the bottom left corners when they are deemed significant at the 95 per cent level.

each voxel and the elements of every row of \mathbf{K} will be the numerical values of the integral of the kernel $K(\mathbf{x})$ over those voxels.

Eq. (9) remains beholden to the usual assumption of linearity in linking the model perturbation \mathbf{m} to the data \mathbf{d} . Acknowledging that the data may be contaminated by noise \mathbf{n} , the inverse problem is defined as requiring us to find the best choice of \mathbf{m} by which to reduce the data misfit, the squared ℓ_2 norm $\|\mathbf{K} \cdot \mathbf{m} - \mathbf{d}\|_2^2$, to the noise level, $\|\mathbf{n}\|_2^2$. Because the data are incomplete, the problem is ill-posed and infinitely many such models exist. Additional conditions need to be imposed to arrive at a unique and physically acceptable solution. This is often done by adding a penalty term $\mathcal{P}(\mathbf{m})$ to the data misfit, which leads to the functional

$$\mathcal{F}(\mathbf{m}) = \|\mathbf{K} \cdot \mathbf{m} - \mathbf{d}\|_2^2 + \mathcal{P}(\mathbf{m}), \quad (10)$$

which is to be minimized. The role of the penalty term is to ensure that \mathcal{F} has a unique and acceptable minimizer. The trade-off between data fit and *a priori* information is encoded in the penalty $\mathcal{P}(\mathbf{m})$. A convenient and often advocated choice for $\mathcal{P}(\mathbf{m})$ is a multiple of the norm-squared of the Laplacian of the model, $\mathcal{P}(\mathbf{m}) = \lambda \|\nabla^2 \mathbf{m}\|_2^2$, which favours smoothness in the solutions (see, e.g. Yanovskaya

& Ditmar 1990; VanDecar & Snieder 1994). The equations for the minimum of $\mathcal{F}(\mathbf{m})$ remain linear,

$$\mathbf{K}^T \cdot \mathbf{K} \cdot \mathbf{m} + \lambda (\nabla^2)^T \nabla^2 \mathbf{m} = \mathbf{K}^T \cdot \mathbf{d}, \quad (11)$$

and can thus be handled by standard algorithms. The trade-off parameter λ needs to be carefully chosen (Hansen 1992).

The novelty now is that we should be able to use model sparsity rather than smoothness as prior information, though we should qualify this statement by the admission that the choice of wavelet basis itself (D4, CDF 4–2, and so on) introduces a certain level of smoothness that is built into the representation itself. As discussed in Section 3 seismic tomographic models may be very well represented by a sparse wavelet expansion. Incorporating this knowledge from the start may therefore lead to important benefits to the behaviour of the inversion scheme. In the following we shall assume that we have chosen a particular family of wavelet and scaling basis functions, see Section 2, to represent and build the unknown model. Below we describe an algorithm that dynamically chooses, based on the data, the number, position and magnitude of the non-zero coefficients with respect to this basis as it iterates (i.e. during the

inversion, not beforehand). Once the family of wavelet functions is chosen, the selection of the non-zero coefficients is therefore part of the inversion algorithm itself. The choice of the non-zero coefficients is not a pre-processing step: the representation of the unknown model is both parsimonious and data-driven, much like in partition-modelling approaches (Bodin *et al.* 2009; Bodin & Sambridge 2009). On the other hand, the choice of basis is made up front, and bases of smooth functions will introduce smoothness in the model (e.g. when, due to absence of data, a whole region can be well approximated using a single large-scale smooth wavelet function).

With the model $m(\mathbf{x})$ expanded in our wavelet basis via the transform S as in the notation of Section 3, and the individual basis functions collected in the columns of a matrix \mathbf{S} , the synthesis map, the pixel-basis model vector \mathbf{m} is

$$\mathbf{m} = S(\mathbf{w}) = \mathbf{S} \cdot \mathbf{w}, \quad (12)$$

with \mathbf{w} the vector of expansion coefficients in the wavelet basis. In having previously defined our construction in terms of a discrete wavelet transform we do not need to devise a separate form of discretization for each of the many choices of wavelet bases that are available to us. In this flexible approach we define the grid size of the cubed sphere at the outset and we are thus able to switch between the various wavelet bases without much additional effort. As we shall remark later on, \mathbf{S} will usually be provided as a (fast) software algorithm and not as a matrix *per se*. We shall also see that the seismic inversions only require application of \mathbf{S} and its transpose \mathbf{S}^T . The inverse \mathbf{S}^{-1} , the analysis map, is not required to be known—or even exist, as is the case for a redundant set of basis functions.

The sparsity of the model parameters \mathbf{w} can now be encouraged by choosing the penalty \mathcal{P} to be proportional to the number of non-zero entries in \mathbf{w} , which we write as $\|\mathbf{w}\|_0$ for short. The functional to be minimized then becomes

$$\mathcal{F}_0(\mathbf{w}) = \|\mathbf{K} \cdot \mathbf{m} - \mathbf{d}\|_2^2 + \lambda \|\mathbf{w}\|_0. \quad (13)$$

We define the solution to the inverse problem as

$$\hat{\mathbf{w}} = \arg \min_{\mathbf{w}} (\|\mathbf{K} \cdot \mathbf{S} \cdot \mathbf{w} - \mathbf{d}\|_2^2 + \lambda \|\mathbf{w}\|_0), \quad (14)$$

and the reconstructed model is

$$\hat{\mathbf{m}} = \mathbf{S} \cdot \hat{\mathbf{w}}. \quad (15)$$

The functional in eq. (14) however is not convex: there exist local minima which makes the minimization much less feasible than solving a system of linear equations. Despite this an iterative algorithm based on hard thresholding exists (Blumensath & Davies 2008, 2009), as briefly discussed by Loris *et al.* (2010).

An alternative, and computationally much more tractable, method for imposing model sparsity in a given basis is to use an ℓ_1 norm penalty (Daubechies *et al.* 2004; Donoho 2006; Bruckstein *et al.* 2009). By identifying $\|\mathbf{w}\|_1 = \sum_i |w_i|$, and choosing $\mathcal{P} = 2\lambda \|\mathbf{w}\|_1$ for the penalty function, then

$$\mathcal{F}_1(\mathbf{w}) = \|\mathbf{K} \cdot \mathbf{S} \cdot \mathbf{w} - \mathbf{d}\|_2^2 + 2\lambda \|\mathbf{w}\|_1 \quad (16)$$

is to be minimized. This functional is convex: a local minimum is automatically a global minimum. This minimum is not necessarily identical to global minimum in eq. (14), but mathematical conditions on the matrix \mathbf{K} exist that guarantee this (Donoho 2006). The important point is that minimizing eq. (16) is a tractable way of obtaining a model with many coefficients exactly equal to zero.

The functional (16) is not differentiable but because \mathcal{F}_1 is the sum of a differentiable and a separable non-differentiable part, convex optimization techniques can find $\hat{\mathbf{w}} = \arg \min_{\mathbf{w}} \mathcal{F}_1(\mathbf{w})$ and the corresponding model (15) with reasonable efficiency. Indeed the iteration

$$\mathbf{w}_{n+1} = \mathcal{U}[\mathbf{w}_n + \beta_n(\mathbf{w}_n - \mathbf{w}_{n-1})], \quad (17a)$$

$$\mathcal{U}(\mathbf{w}) = \mathcal{T}_{\alpha\lambda}[\mathbf{w} + \alpha \mathbf{S}^T \cdot \mathbf{K}^T \cdot (\mathbf{d} - \mathbf{K} \cdot \mathbf{S} \cdot \mathbf{w})], \quad (17b)$$

converges to the minimizer of (16), as shown by Beck & Teboulle (2009). Here $\mathcal{T}_{\alpha\lambda}$ now stands for ‘soft’ thresholding (Mallat 2008) of the coefficients on a component-by-component basis, which is to say $\mathcal{T}_{\tau}(\mathbf{w}) = 0$ for $|\mathbf{w}| \leq \tau$, and $\mathcal{T}_{\tau}(\mathbf{w}) = \mathbf{w} - \tau \operatorname{sgn}(\mathbf{w})$ for $|\mathbf{w}| > \tau$. This is a non-linear operation. The parameter α in eq. (17b) can be chosen as the reciprocal of the largest eigenvalue of $\mathbf{S}^T \cdot \mathbf{K}^T \cdot \mathbf{K} \cdot \mathbf{S}$. We choose $t_0 = 1$ and

$$\beta_n = (t_n - 1)/t_{n+1}, \quad (17c)$$

$$t_{n+1} = (1 + \sqrt{1 + 4t_n^2})/2. \quad (17d)$$

A non-iterative direct algorithm also exists (Efron *et al.* 2004; Loris 2008), but because of the large problem sizes typically encountered in seismic tomography, we focus here on this so-called fast iterative soft thresholding algorithm (FISTA). It has an $1/n^2$ rate of convergence to $\mathcal{F}_1(\hat{\mathbf{w}})$, which is in a sense optimal. The algorithm (17) was used by Loris *et al.* (2010) on a 3-D toy tomographic model. There is however a typographical error in that work, which missed the factor 4 under the square root in eq. (17d).

The iterative algorithm (17) requires only two linear maps, and their transposes. First there is the linear map from model to data space, given by the matrix \mathbf{K} in eq. (9). The second is the linear map \mathbf{S} from model parameters to model space, eq. (12). This map is typically available in the form of a (fast) algorithm, *in casu* the inverse wavelet transform S , rather than explicitly in matrix form. Each iteration step of algorithm (17) requires one application of \mathbf{K} , \mathbf{K}^T , \mathbf{S} and \mathbf{S}^T each. Eqs (17a–d) demonstrate that the iterative inversion algorithm does not require the inverse of the map \mathbf{S} , much as it does not require the inverse of \mathbf{K} . Moreover, neither \mathbf{S} nor \mathbf{K} need be invertible. As already mentioned, this means that a model may be represented by a sparse superposition of a redundant set of functions in which the expansion of the model is no longer unique. For example, redundant dual-tree wavelets were used in a synthetic tomography experiment by Loris *et al.* (2007).

In practice it is advisable to keep $\mathbf{K} \cdot \mathbf{S}$ and $\mathbf{S}^T \cdot \mathbf{K}^T$ in eq. (17b) in factorized form. One can easily switch bases by modifying \mathbf{S} and rerunning the inversion algorithm. No new matrix $\mathbf{K} \cdot \mathbf{S}$ needs to be pre-computed, which is important given that \mathbf{K} may have several hundreds of thousands of rows. This is particularly useful in the case of sparse reconstructions, where the choice of basis itself (e.g. D4, CDF 4–2 and so on, and this before the inversion determines which members of the basis set most usefully contribute to the solution) is one of the factors to be assessed by prior evaluation of the performance of synthetic model inversions or by inspection during the inversion. In other words, the iterative inversion procedure can be performed for a number of different choices of wavelet families. Section 3 made it clear that using model sparsity as *a priori* information depends on the details of the basis used. Setting up the inversion software in this manner is therefore forward-looking as new transforms can easily be incorporated later on. Examples of emerging techniques that can be evaluated in this

context are curvelets and shearlets (Candès *et al.* 2005; Labate *et al.* 2005; Easley *et al.* 2008), which offer better directional sensitivity than classical wavelet transforms but are redundant. The described flexibility of this approach was one of our major design requirements and will yield many dividends in future applications.

6 A SECOND CONSTRUCTION

In principle we are now ready to apply the first family of wavelet constructions on the cubed sphere that we introduced in Section 2 to the inverse problem in the manner outlined in Section 5. As shown in Section 3 we expect our solutions to be sparse, and as discussed in Section 4 we will be able to use this sparsity and the location- and scale-dependence of the results to make geophysical inference about the structure of seismic heterogeneity in the Earth.

As we recall, our First Construction entailed defining wavelet and scaling functions on a single chunk $\xi, \eta \in [-\pi/4, \pi/4]$ and then mapping them onto the sphere using eq. (1). By this definition the basis functions live on a single chunk. Without the modifications and preconditioning of the basis at the boundaries between the chunks that we introduced, sharp discontinuities in the behaviour of the coefficients occur at the chunk edges; making the transforms edge-cognizant, as we did in the manner of Cohen *et al.* (1993), required special tailoring of the transforms. This is often cumbersome and in general harms our stated goal of keeping our procedure flexible enough to be able to switch from one wavelet family to another which might be more suitable with hindsight. In addition, the interval wavelet transforms that we used so far are not norm-preserving. Extensive experimentation with such bases revealed that despite their qualities in the representation of geophysical functions, that is, in performing the forward mappings, when used for the inverse problem the solutions obtained using eq. (17) were plagued by unsightly artefacts at the seams between chunks. These we do not show as they appeared predominantly in synthetic tests with simple, isolated ‘phantoms’ where their nature was immediately obvious; as the density of path coverage increases and the target structure becomes more Earth-like, their presence becomes harder to distinguish visually. Presumably the ℓ_1 -thresholding could be adapted locally to counter this effect, but to be truly practical we should not have to resort to this. We thus desire a mechanism to map any localized basis function defined on a Cartesian grid to the sphere, with smoothness even across chunk boundaries. Here we present a straightforward, universal method that accomplishes this.

As opposed to the geometry of the Ronchi *et al.* (1996) cubed sphere shown in Fig. 1, we now cover the sphere with six larger chunks, by extending the coordinates by 50 per cent on each chunk, to $\tilde{\xi}, \tilde{\eta} \in [-3\pi/8, 3\pi/8]$, see Fig. 10. We shall refer to these partially overlapping domains as ‘superchunks’. In $(\tilde{\xi}, \tilde{\eta})$ coordinates they are simply six large squares (rather: cubes if we take the radial direction into account also), with the ‘original’ chunks at their centres. Functions defined on this central part can now smoothly cross into the outer part, that is, they are allowed to spill over into another chunk while staying in the same superchunk. Fig. 11 shows a selection of examples where this is the case. The smoothness of the functions across the boundaries is apparent, though we note that if we were to plot them in the manner in which Fig. 2 was presented, they would appear to have kinks in them; this is simply because the coordinate transform of eq. (1) itself is non-smooth.

To map a function defined on a single superchunk $\tilde{\kappa} = 1 \rightarrow 6$ to the corresponding chunk and its neighbours, one loops over all the voxels in this central chunk and its four neighbours. The centre of each such voxel (ξ, η, r, κ) is mapped to (x, y, z) coordinates using

Figure 10. Aerial view showing our second adaptation of the cubed sphere of Ronchi *et al.* (1996). The black lines identify the boundaries of the six chunks that were apparent also in Fig. 1. The blue lines correspond to the boundaries of the overlapping ‘superchunks’ as discussed in the text.

formula (1). In the same way as eq. (2) we then calculate

$$(\tilde{\xi}, \tilde{\eta}) = \begin{cases} [\text{atan}(z/y), \text{atan}(-x/y)] & \text{if } \tilde{\kappa} = 1, \\ [\text{atan}(y/x), \text{atan}(-z/x)] & \text{if } \tilde{\kappa} = 2, \\ [\text{atan}(-y/z), \text{atan}(x/z)] & \text{if } \tilde{\kappa} = 3, \\ [\text{atan}(x/z), \text{atan}(-y/z)] & \text{if } \tilde{\kappa} = 4, \\ [\text{atan}(-z/x), \text{atan}(y/x)] & \text{if } \tilde{\kappa} = 5, \\ [\text{atan}(-x/y), \text{atan}(z/y)] & \text{if } \tilde{\kappa} = 6, \end{cases} \quad (18)$$

to convert these (x, y, z) to the $(\tilde{\xi}, \tilde{\eta}, \tilde{r} = r)$ coordinates in the superchunk $\tilde{\kappa}$, limited to $-3\pi/8 \leq \tilde{\xi}, \tilde{\eta} \leq 3\pi/8$. This then determines which voxel in the superchunk is mapped to the voxel in the original chunk. The index of the voxel in each superchunk $\tilde{\kappa}$ is

$$i = 1 + \left\lfloor \left(\tilde{\xi} + \frac{3\pi}{8} \right) \frac{2N}{\pi} \right\rfloor, \quad j = 1 + \left\lfloor \left(\tilde{\eta} + \frac{3\pi}{8} \right) \frac{2N}{\pi} \right\rfloor, \quad (19)$$

where N is the number of voxels in the ξ and η directions of a chunk and $\lfloor \cdot \rfloor$ indicates rounding down. Voxel indices run from $1 \rightarrow N$ in an original chunk and from $1 \rightarrow 3N/2$ in a superchunk. The central part of a superchunk is a copy of the original chunk, whereas the voxels outside the centre of a superchunk are mapped to neighbouring chunks. As the superchunks partially overlap, a chunk voxel on the sphere may receive contributions from up to three superchunks: a voxel near a chunk corner may receive three contributions, a voxel near a chunk edge may receive two, and voxels near chunk centres only one. The identifications are most easily made by table look-up.

In Fig. 11 we show a number of wavelet functions from this Second Construction at a variety of locations. These now map smoothly to the sphere. The wavelets shown here are from the Cohen *et al.* (1992) CDF 4–2 wavelet family, as in Fig. 4. These are mirror-symmetric in the (ξ, η) domain, but they are no longer orthogonal. As in Section 2 the wavelets at a fixed scale are not rotations of each other on the sphere, but rather translates in the superchunk $(\tilde{\xi}, \tilde{\eta})$ domain. This effect is most notable for the wavelet and scaling

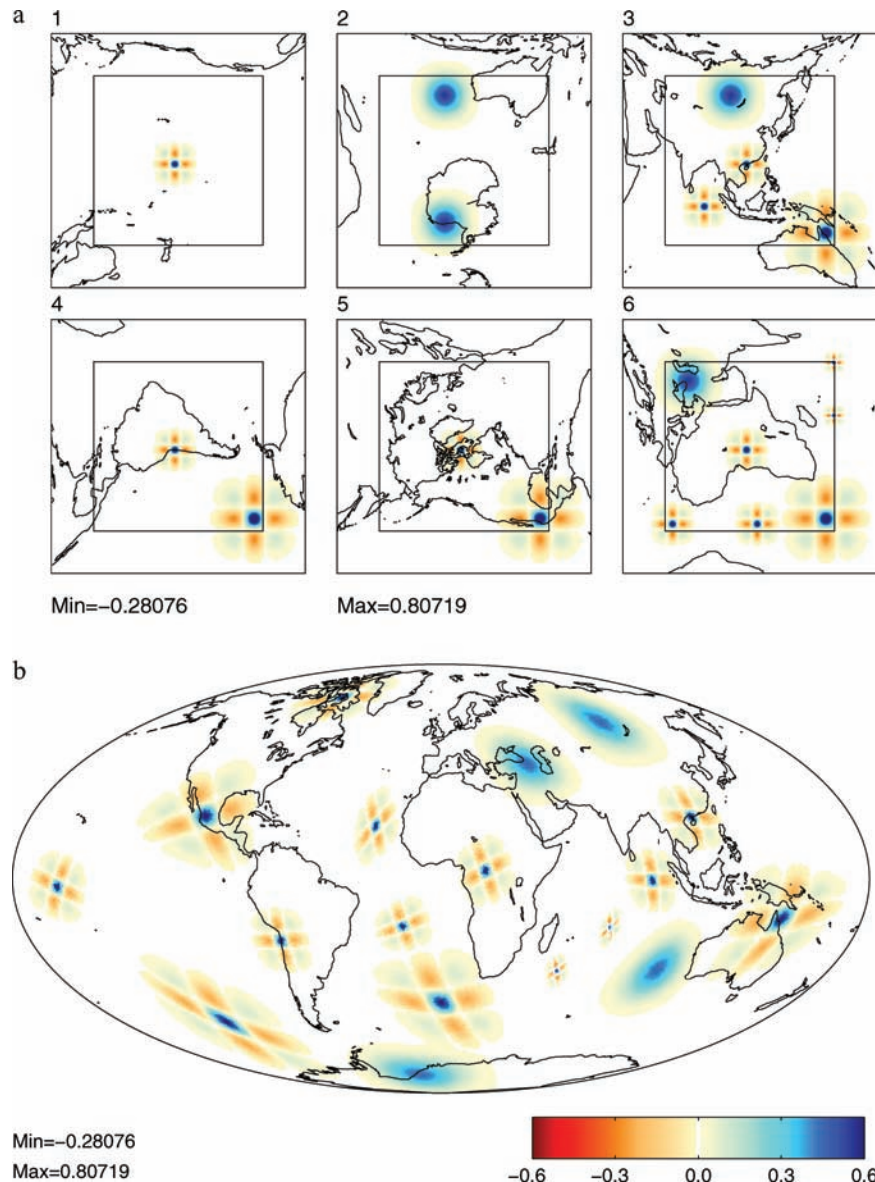

Figure 11. (a) Six superchunks, as defined in Fig. 10, with a number of wavelet and scaling functions defined on them. (b) The same functions mapped to the sphere by the procedure described in Section 6. They are smooth everywhere.

functions that are located on or near chunk edges, specifically near the corners. Basis functions that have the same norm in the superchunk domain may not have the same norm in the chunk domain.

7 NUMERICAL EXPERIMENTS

We consider a set of great-circle paths that is a global collection of 2469 earthquakes and 199 stations yielding 8490 surface wave paths, a situation based on, if not identical to, the ray path coverage in the models of Rayleigh-wave phase speeds at 80 s period obtained by Trampert & Woodhouse (1995, 1996, 2001). For simplicity we convert this path coverage to the ray-theoretical values of arrival-time sensitivity expressed in our model domain. The image in Fig. 12 (top panel) renders all rays in this data set of realistically heterogeneous global seismic sensitivity. For synthetic input model we chose a single interval of the Montelli *et al.* (2006) model centred on 722 km depth, shown in Fig. 12 (second from the top). In addition, and an admitted departure from realism, we select four

circular regions of null structure. Their purpose is to test the inversion algorithm and the choice of basis when sharp wave speed contrasts are known to be present in the true model. We calculate the traveltime perturbations over these 8490 ray paths and add Gaussian noise to them with an rms value that is 10 per cent of that of the rms of the data. The variance of this noise is denoted σ^2 .

The reconstruction is by the algorithm (17) using the four-level CDF 4–2 wavelets under the Second Construction by which smooth chunk crossings were enabled, as shown in Fig. 11. In keeping with the description of Section 5 the dual aim is to satisfy the noisy data in the traditional ℓ_2 sense while favouring a model that is sparse in the wavelet basis by minimizing the ℓ_1 norm of the coefficients. Fig. 12 (third from the top) shows the obtained solution. Of the $6 \times 128^2 = 98\,304$ degrees of freedom in this parametrization the algorithm terminates on a model with 1670 non-zeros. Due to lack of data, the relative output error is high: 33.5 per cent.

The behaviour of the solution through the 1000 iterations is shown in Fig. 12 (bottom panel), which plots the ℓ_1 norm of the wavelet

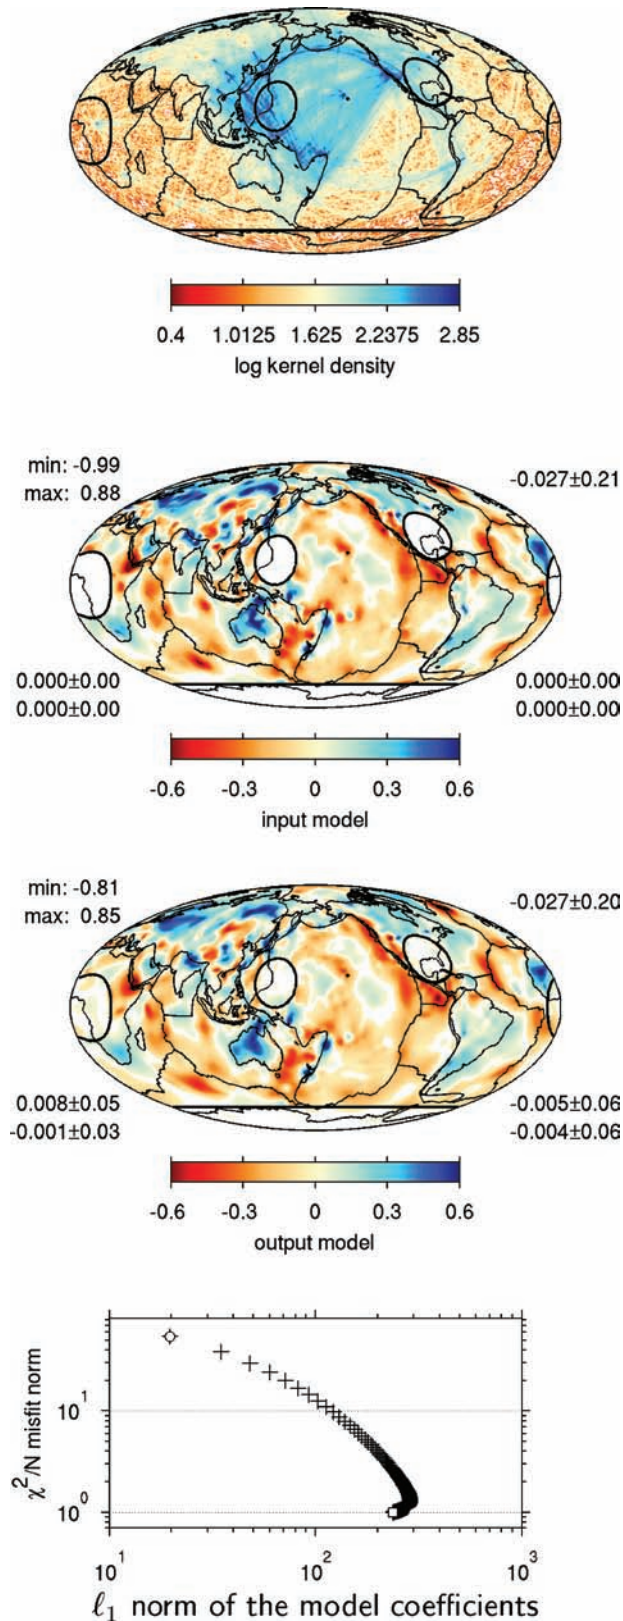

Figure 12. Synthetic experiment under realistic conditions with a twist, illustrating the recovery of a seismic tomographic model with artificially introduced blank spots from noisy data, using the Second Construction discussed in Section 6 and the iterative algorithm of Section 5. The solution after one iteration is represented by the filled white circle in the bottom panel; the solution after 1000 iterations by the filled white square.

coefficients against a measure of the evolving misfit calculated as the reduced chi-square

$$\frac{\chi^2}{N} = \frac{\|\mathbf{d} - \hat{\mathbf{d}}\|_2^2}{\sigma^2 \|\mathbf{d}\|_0} = \frac{\|\mathbf{d} - \mathbf{K} \cdot \hat{\mathbf{m}}\|_2^2}{\sigma^2 \|\mathbf{d}\|_0}, \quad (20)$$

in other words, the squared ℓ_2 norm of the data misfit normalized by the noise variance and the total number of data constraints, for which it is reasonable to assume (Nolet 2008) that it is distributed as a χ_1^2 variable, with mean 1. The starting point of the iteration is marked by the filled white circle, and the final solution by the filled white square, which is arrived at when the χ^2/N variable in eq. (20) reaches its expectation 1. Every one of the 1000 iterates in the sequence is marked by a black cross. As we note the algorithm (17) rapidly reduces the data misfit in the first few steps, slowing down after that, at the same time increasing the sum of the absolute values of the wavelet coefficients. After turning a corner in this space, the remainder of the time spent is in reducing the ℓ_1 norm of the coefficients of the solution while slowly converging to the target reduced chi-square of $\chi^2/N = 1$.

The solution is very good; the input model is well matched and the leakage of the solution into the areas where no structure should be recovered is relatively minor. The global map views in Fig. 12 had all values that fall below a threshold of 1/20th of their maximum absolute value rendered white for visual guidance, and they receive several additional annotations for us to be able to judge the quality of the solution quantitatively. The minimum and maximum values of the models are quoted in the top left corner, and in the top right corner we show their mean and the rms values. The four sets of numbers in the bottom left- and right-hand corners quote these same metrics for the areas contained inside of the circular areas. As the input model has no structure there, all of these are zeroes. This is no longer the case for the output which serves as our way to evaluate the leakage of the solution into those areas. As we can see the comparison is very favourable.

While we have conducted numerous synthetic tests with a multitude of synthetic input models (including checkerboard tests, Gaussian shaped anomalies positioned at various locations, and using a variety of ray path coverages), only one of these tests is reported here. As noted by Loris *et al.* (2007, 2010) there are more algorithms available to us than the one described in eq. (17), and as we have argued in this paper there is a wealth of wavelet constructions that can be brought to bear on the inverse problem of global seismic tomography. All of these alternatives remain in principle candidates to be implemented using our First or Second Construction for wavelets on the sphere. A more detailed comparison of their relative performance is to be reported in forthcoming work. It is there also that we will fully integrate the third dimension into our formalism. Conceptually, there is no difficulty in doing this: we have transformed the ball of the Earth into six independent or partially overlapping Cartesian model domains with three separable coordinates. Taking into account the depth dimension merely involves applying a third wavelet transform to the result of the transform in the two angular coordinates, but as there remain choices to be made, a thorough discussion remains outside the scope of this paper.

8 CONCLUSIONS

Until now, seismic wave speed models of the Earth have been routinely parametrized in terms of spherical harmonics, networks of tetrahedral nodes, rectangular voxels or spherical splines. However, there were few approaches to earth model parametrization

by wavelets on the 3-D ball. To the rich field of wavelets on the ball or its surface, the sphere, we have contributed two new flexible constructions that are eminently suited to solve seismological tomographic inverse problems.

To form the numerical grid we considered a surface tessellation known as the ‘cubed sphere’, popular in fluid dynamics and computational seismology, which can be combined with a (semiregular) radial subdivision. This mapping transforms the entire volume of the mantle into six portions. In the new variables, these ‘chunks’ correspond to rectangular boxes with Cartesian coordinates. Standard algorithms can then be used to perform the wavelet transformation (or any other) in each of the six bounded volumes. We developed two possible classes of discrete wavelet transforms in the angular dimension of the cubed sphere. One relies on preconditioning and special boundary filters to account for the edges separating the chunks; another broadens the definition of the cubed sphere to include chunks that partially overlap, on which we implement standard wavelet transforms.

Much has been gained by our design of procedures that efficiently parametrize the seismological inverse problem. First, the multiresolution character of a wavelet basis allows for the models to be represented with an effective spatial resolution that varies as a function of position within the Earth. Secondly, inversion schemes that are formulated in terms of wavelets can exploit recent theoretical and numerical advances by which the most sparse solution vector, in wavelet space, is found through iterative minimization of a combination of the ℓ_2 (to fit the data) and ℓ_1 norms (to promote sparsity in wavelet space).

In preparation for the continuing increase in high-quality seismic data that is expected in the decades to come, our focus has also been on numerical efficiency and the ability to use parallel computing in constructing the model. We have shown how seismic model representation behaves under progressive thresholding of the wavelet coefficients, and how the geographically distributed power of published seismic models varies over the scale lengths that can be independently resolved. Synthetic tests under realistic conditions validate the approach that we advocate for the future of seismic tomography, which shows the ability to explain heterogeneous, massive data sets under the constraint that the best-fitting models should also be sparse in the wavelet bases used.

ACKNOWLEDGMENTS

We thank Huub Douma, Massimo Fornasier and Yves Wiaux for valuable discussions throughout the past several years, and the Editor-in-Chief, Jeannot Trampert, one anonymous reviewer and Malcolm Sambridge for advice which helped improve the manuscript. Comments by Sujoy Mukhopadhyay and Chris Harig inspired aspects of two of the figures. FJS was supported by Princeton University account 195-2142 (thanks to Debbie Fahey!) while enjoying the hospitality of the Vrije Universiteit Brussel and the Katholieke Universiteit Leuven in the Summer of 2010, where the writing-up started. IL is ‘chercheur qualifié’ of the F.R.S.-FNRS (Belgium). Portions of this research were supported by VUB-GOA grant 062 to ICD and IL, the FWO-Vlaanderen grant G.0564.09N to ICD and IL and by NSF grant CMG-0530865 to ICD, GN and F. A. Dahlen. GN and JC received support from the ERC (Advanced grant 226837) and a Marie Curie Re-integration Grant (project 223799).
